## **Abstract**

As part of NOAA's tsunami forecast system, this study addresses the development, validation, and stability tests of a tsunami forecast model for King Cove, Alaska. Based on the Method of Splitting Tsunami (MOST), the developed model is constructed at a spatial resolution of 20 m in the finest grid to accomplish 4-hour simulation of wave inundation onto dry land within minutes of CPU time. A reference inundation model is developed in parallel using grids of higher resolution up to 10 m to provide modeling references for the forecast model. The model validation shows the comparable results between the model computation and observations for events that are less affected by the local wave climate. The comparison between model and measurements for small tsunami events at an order of cm is dominated by the noise level of the tide gauge records. The forecast model provides quantitative estimation of the inundation, runup and computed maximum values for these events. The stability of the forecast model is evaluated based on 44 synthetic scenarios generated in all subduction zones of the Pacific Rim at different levels of  $M_w$  9.3. Model computation shows that such magnitudes can potentially generate a maximum tsunami wave up to 7 m high along the coastline of King Cove.

## **1. Introduction**

The National Oceanic and Atmospheric Administration (NOAA) Center for Tsunami, Research (NCTR) at the NOAA Pacific Marine Environmental Laboratory (PMEL) has developed a tsunami forecasting capability for operational use by NOAA's two Tsunami Warning Centers located in Hawaii and Alaska (Titov *et al.*, 2005). The system is designed to efficiently provide basin-wide warning of approaching tsunami waves accurately and quickly. The system, termed Short-term Inundation Forecast of Tsunamis (SIFT), combines real-time tsunami event data with numerical models to produce estimates of tsunami wave arrival times and amplitudes at a coastal community of interest. The forecast system integrates several key components: deep-ocean observations of tsunamis in real time, a basin-wide pre-computed propagation database of water level and flow velocities based on potential seismic unit sources, an inversion algorithm to refine the tsunami source based on deep-ocean observations during an event, and high resolution tsunami forecast models.

Being one of the most seismically active regions of the world, Alaska has the greatest earthquake and tsunami potential in the entire United States (Suleimani *et al.*, 2002). The Alaska-Aleutian Subduction Zone, where the Pacific Plate is subducting under the North America Plate, has great potential in generating both local and basin-wide tsunamis that threaten the coastal communities of Alaska and the Pacific. Historical tsunamis have had

a devastating impact on the Alaskan coastline. Tsunami forecast models in Alaska play an important role in the forecast system by expediting estimates of the tsunami impact on populous coastlines and better prepare local communities for potential risks. The main objective of this work is to develop a tsunami forecast model for King Cove to maximize the length of time that the community has to react to a tsunami threat by quickly providing accurate information to emergency managers and other officials responsible for the community and infrastructure. An additional goal is minimization of false alarms that ultimately erode system credibility with the resident and fishing populations. Detailed discussion of individual components of the King Cove forecast model are provided in the report; including the development of grids using bathymetry and topography, model validation using historical tsunami cases, model stability and robustness, sensitivity testing using synthetic tsunami events, the basic model setup, and model parameters.

## **2. Forecast Methodology**

A high resolution inundation model was used as the basis for development of a tsunami forecast model to operationally provide an estimate of wave arrival time, wave height, and inundation at King Cove following tsunami generation. All tsunami forecast models are run in real time while a tsunami is propagating across the open ocean. The King Cove model was designed and tested to perform under stringent time constraints given that time is generally the single limiting factor in saving lives and property.

The general tsunami forecast model, based on the Method of Splitting Tsunami (MOST), is used in the tsunami inundation and forecasting system to provide real-time tsunami forecasts at selected coastal communities. The model runs in minutes while employing high resolution grids constructed by the National Geophysical Data Center. The Method of Splitting Tsunami (MOST) is a suite of numerical simulation codes capable of simulating three processes of tsunami evolution: earthquake, transoceanic propagation, and inundation of dry land. The MOST model has been extensively tested against a number of laboratory experiments and benchmarks (Synolakis *et al.*, 2008) and was successfully used for simulations of many historical tsunami events. The main objective of a forecast model is to provide an accurate, yet rapid, estimate of wave arrival time, wave height, and inundation in the minutes following a tsunami event. Titov and González (1997) describe the technical aspects of forecast model development, stability, testing, and robustness, and Tang *et al.* (2009) provide detailed forecast methodology.

A basin-wide database of pre-computed water elevations and flow velocities for unit sources covering worldwide subduction zones has been generated to expedite forecasts (Gica *et al.*, 2008). As the tsunami wave propagates across the ocean and successively

reaches tsunami meter observation sites, recorded sea level is ingested into the tsunami forecast application in near real-time and incorporated into an inversion algorithm to produce an improved estimate of the tsunami source. A linear combination of the pre-computed database is then performed based on this tsunami source, now reflecting the transfer of energy to the fluid body, to produce synthetic boundary conditions of water elevation and flow velocities to initiate the forecast model computation.

Accurate forecasting of the tsunami impact on a coastal community largely relies on the accuracies of bathymetry and topography and the numerical computation. The high spatial and temporal grid resolution necessary for modeling accuracy poses a challenge in the run-time requirement for real-time forecasts. Each forecast model consists of three telescoped grids with increasing spatial resolution in the finest grid, and temporal resolution for simulation of wave inundation onto dry land. The forecast model utilizes the most recent bathymetry and topography available to reproduce the correct wave dynamics during the inundation computation. Forecast models, including the King Cove model, are constructed for at-risk, populous coastal communities in the Pacific and Atlantic Oceans. Previous and present development of forecast models in the Pacific (Titov *et al.*, 2005; Titov, 2009; Tang *et al.*, 2009 & 2012; Wei *et al.*, 2008 & 2012) have validated the accuracy and efficiency of each forecast model currently implemented in the real-time tsunami forecast system. Models are continuously tested when the opportunity arises and are used for scientific research.

## 2.1 Forecast Area

King Cove is ranked highly amongst Alaska coastal communities prioritized for tsunami hazard mapping (Suleimani *et al.*, 2002). It is a small community with 756 residents located on the Pacific side of Alaska Peninsula and the local economy depends almost completely on the year-round commercial fishing and seafood processing industries. Figure 1 provides an overview of the main residential areas and harbor facilities in King Cove. With elevation less than 6 m, most of the residents are living in a low-lying area prone to tsunami inundation. King Cove has a small boat harbor that can hold 50 vessels up to 18 m in length, and a large boat harbor that can hold 46 vessels up to 46 m in length.

The NOS tide station at King Cove is located at with a water depth of about 3 m in the large boat harbor (Figure 2). Although the tide station was established as early as 1917, the present installation was not in position until August 2005. During the 1946 Unimak tsunami, an eyewitness reported a maximum tsunami wave amplitude of 1.5 m at King Cove. Lander (1996) also reported that light damage occurred at the False Pass

cannery, and that the tsunami was approximately 3 m high when it arrived at King Cove. The largest observed tsunami wave amplitude at King Cove after the 1946 event is 62 cm during the 2010 Chile tsunami (Table 1). The up-to-date tsunami data recorded at King Cove is available for 7 trans-ocean events since 2006, which will be used for model validation in this study, including the 3 May 2006 Tonga, the 15 November 2006 Kuril, the 15 August 2007 Peru, the 29 September 2009 Samoa, the 27 February 2010 Chile, the 11 March 2011 Japan and the 27 October 2012 Haida Gwaii tsunamis. Figure 3 labels the origins of these tsunami events, which are used for validation of the forecast model.

## 2.2 Bathymetric and topographic DEMs

Accurate bathymetry and topography in offshore and coastal regions play the key role, globally and locally, in tsunami generation, propagation and inundation. Currently, the global bathymetric and topographic datasets are available for public-domain research. Marks and Smith (2006) conducted an evaluation on 6 publicly available global bathymetry grids: DBDB2 (Digital Bathymetric Data Base by Naval Research Laboratory), ETOPO2 (Earth Topography by National geophysical Data Center), GEBCO (General Bathymetric Charts of the Oceans by British Oceanographic Data Center), GINA (Geographic Information Network of Alaska), Smith and Sandwell (1997) and S2004. They concluded the original Smith and Sandwell (1997) grid might be the best source among these global bathymetric grids. Subsequently they developed a new 1-min global topography grid S2004 that combines the Smith and Sandwell (1997) below 1000m depth and equatorward of 72° and GEBCO grids in shallow water and polar region. NOAA Center for Tsunami Research (NCTR) developed a Pacific-Basin 30sec grid, derived primarily the Smith and Sandwell grid and the SRTM30\_PLUS grid, with amendments in areas where NCTR has better bathymetry. This comprehensive dataset covers the entire Pacific Ocean and part of the Arctic Ocean from 120°E to 68°W, and 80°S to 80°N.

While developing bathymetric and topographic grids for a few coastal sites, NCTR has been collaborating with National Geographic Data Center (NGDC) in the Tsunami Inundation Gridding Project since 2005 to build high resolution digital elevation models for more U.S. coastal regions, and satisfy the needs of forecast model development in the near future. Along with the associated documentation, the finished datasets are available in ESRI ArcGIS ASCII grid format at <http://www.ngdc.noaa.gov/dem/>.

The King Cove DEM was developed by NGDC in 2007 with 1/3 arc sec grid resolution covering an area of 161.8°W to 162.8°W, 54.45°N to 55.35°N. The horizontal and vertical datum of the dataset are the World Geodetic System 1984 (WGS 84) and the

mean high water (MHW), respectively. As requested by NCTR, this digital elevation model was updated in 2008 for more accurate description on the two boat harbors and the waterway connecting the northern boat harbor and residential area (Carignan et al., 2009). The topography data of NGDC's digital elevation model was obtained from a combination of USGS NED, NASA SRTM and NGDC digitized harbor features. Readers are referred to Carignan et al. (2009) for details of the developed digital elevation model. The King Cove digital elevation model has an estimated vertical accuracy of 10-15 meters for the island interiors derived from NED topographic data, and about 10-16 m from the SRTM topography (Carignan et al., 2009). The lack of Lidar data in the digital elevation model may cause errors in the model computation, especially when onshore flooding occurs.

The King Cove forecast model consists of three telescoped grids with increasing spatial, 20 m in the finest grid, and temporal resolution for simulation of wave inundation onto dry land. The bathymetry and topography used in the development of this forecast model was based on a digital elevation model provided by the NGDC and the author considers it to be an adequate representation of the local topography/bathymetry. As new digital elevation models become available, forecast models will be updated and report updates will be posted at [http://nctr.pmel.noaa.gov/forecast\\_reports/](http://nctr.pmel.noaa.gov/forecast_reports/).

### 2.3 Model Setup

Figures 4 to 9 show the computational grids of the forecast model and reference inundation model that are derived based on these DEMs. Figures 4 and 5 shows the computational domain of the A-grid for both the reference model and the forecast model grids for comparison of bathymetry resolution. Figures 4 and 5 show the bathymetry and topography of the A grid at the grid resolution of 36 arc sec. Both the forecast model and the reference model are using a same grid resolution for A-grid computation; except the domain coverage in the reference model is larger than that of forecast model (the red box in Figure 3 indicates the forecast model A-grid domain). The southern boundary of both A grids is placed offshore of the Aleutian Trench to ensure a less affected transition between linear and nonlinear wave dynamics. It also allows a smooth adoption of the boundary conditions from the pre-computed propagation database (Gica et al., 2008). The black box in each plot indicates the coverage of the B-grid shown superimposed over the A-grid domain of the plot. The entire Shumagin Islands are situated on the edge of the Alaska-Aleutian trench, surrounding by water less than 100 m deep. In addition to the contribution from aforementioned strong tectonic activities, the rugged landscape of the southeast of the Alaska Peninsula is also owing to the scouring and grinding of the ice

sheet as once covered by a Pleistocene ice cap. While the tsunami wave propagation is slowed down over the shallow bathymetry, the wave energy in the mean time is also scattered into different directions by the jagged sea floor and serrated coastline.

Figures 6 and 7 show the computational domain of the intermediate B grid, which has an extent of  $1^\circ$  ( $\sim 63$  km) in longitudinal and  $0.8^\circ$  ( $\sim 90$  km) in latitudinal direction.

Figure 6 depicts the bathymetry and topography at the grid resolution of 6 arc sec ( $\sim 106$  m in longitudinal direction and  $\sim 180$  m in latitudinal direction) for the reference model and Figure 7 shows the B grid at 12 arc sec ( $\sim 212$  m in longitudinal direction and  $\sim 360$  m in latitudinal direction) for the forecast model. Both grids are interpolated from the King Cove 1/3 arc sec ( $\sim 5.9$  m in longitudinal direction and  $\sim 10.3$  m in latitudinal direction) dataset developed by NGDC (Taylor et al, 2008). The black box in each plot indicates the coverage of the C grid. As one can see, both B grids provide model computation for King Cove's vicinity on the continental shelf mostly shallower than 100 m.

Figure 8 demonstrates the computational domain of the finest grid, C, with an extent of  $0.09^\circ$  ( $\sim 5.7$  km) in longitudinal and  $0.09^\circ$  ( $\sim 10$  km) in latitudinal direction, with a grid resolution of 1/3 arc sec ( $\sim 5.9$  m in longitudinal direction and  $\sim 10.3$  m in latitudinal direction). To satisfy the computational time requirement, the C grid used in the forecast model is a lot smaller than that of reference model. In forecast model, the C grid is focused on the vicinity of the two boat harbors in King Cove. Figure 9 shows the bathymetry and topography of the C grid with an extent of  $0.035^\circ$  ( $\sim 2.2$  km) in the longitudinal direction and  $0.0239$  ( $\sim 2.7$  km) in the latitudinal direction, with a grid resolution of 2/3 arc sec ( $\sim 11.8$  m in longitudinal direction and  $\sim 20.6$  m in latitudinal direction). Both C grids are interpolated from the King Cove 1/3 arc sec dataset developed by NGDC (Taylor et al, 2008). The location of the NOS tide station is indicated by the red dot. The largest water depth in the bay area is about 40 m, and the deepest part in the northern boat harbor is 10 m.

The model setup and input parameters are detailed in Table 1.

### 3. Results and Discussions

#### 3.1 Model Validation

The DART array plays a critical role in defining the tsunami source (Table 2) and has provided accurate real-time tsunami forecast for U.S. coastlines during nearly 40 events since their establishment in late 90s, especially after 2005. Some of these events were recorded by the King Cove tide gauge. The observed maximum tsunami amplitudes of

each of these events are reported in Table 2 and are used to validate the King Cove model. Figures 10 to 16 show the maximum tsunami wave amplitude and flow speed computed using the forecast model and the reference model. Also shown in these figures, is the comparison between model results and measurements at the King Cove tide station.

Figures 10 to 16 show that the recorded time series at the King Cove tide station is strongly affected by the background noises. These noises could be a result of instrument errors and improper sampling of swell waves. With a magnitude of centimeters and long wave periods, they are hard to distinguish from tsunami signals within the same level. This effect becomes particularly serious at places, like King Cove, that are located in the shadow of tsunami wave energy, but dominated by swell waves during the storm season. For this reason, large events (11 March 2011 Japan and 27 February 2010 Chile) usually show better agreement between model results and observations, while the model results of small events (3 May 2006 Tonga, 15 November 2006 Kuril, 13 January 2007 Kuril, 15 August 2007 Peru, 29 September 2009 Samoa and 27 October 2012 Haida Gwaii) are much less comparable with the measurements. Therefore, the 2010 Chile and 2011 Japan tsunamis are critical events for King Cove model validation where background noise is less dominant. The modeling results of these two events show slight underestimation of the wave amplitudes in comparison with the measurements. The matching of wave period in the first several waves indicates the models can provide simulation of the tsunami-induced harbor resonance, although the models can't fully reproduce the resonant dynamics in the small harbor. The results computed by the reference model using high resolution grids show good agreement with those computed by the forecast model for the first six hours of the model computation. Although the model results between the reference model and forecast model start to show some discrepancies in wave amplitudes after six hours, both models still give consistent results in phase and wave periods. The difference between the reference model and forecast model are primarily attributed to different grid domain coverage and grid resolution in the C grid.

Figures 10 to 16 also plot the maximum water amplitude and maximum current speed computed from the both the reference model and the forecast model for eight historical tsunami events. The maximum wave amplitude in the harbor where the tide station resides is generally larger than in the neighboring harbor and in the bay, but lower than in the lagoon, which traps the waves due to narrowing waterways between the boat harbor and residential areas. One may expect larger tsunami wave inundation on the back of residential areas. The flow speed at the lagoon entrance is usually the largest in King Cove and its vicinity, and ship navigation at the entrance may be a concern for the local community during a tsunami event. It can be observed that nearly every event (except for

the 15 November 2006 Kuril), the reference model shows a slightly smaller maximum wave amplitude in the small harbor. It is likely attributed to the larger domain coverage in its C grid, as well as slightly different harbor response to the incoming tsunami in the reference model and forecast model.

### 3.2 Model stability tests using artificial mega tsunamis

Model stability of the forecast model is studied using 41 synthetic extreme events of  $M_w = 9.3$  generated in each subduction zone around the Pacific Rim (Figure 17 and Table 3). Each scenario imitates an equivalent or greater event of the 2004 Indian tsunami, which caused severe devastation in the coastline of Indian Ocean and accounted for hundreds of thousands of deaths. Each hypothetical tsunami source consists of 20 unit sources, covering a rupture area of 1000 km by 100 km, with an averaged 28.4 m slip coefficient (also termed alpha in Table 3). These scenarios are used to examine the stability of the developed King Cove forecast model under the strike of extreme waves generated by mega tsunamis from all directions.

Figures 18a and 18b provide a composite plot of the computed time series at the King Cove tide station for all synthetic events. The synthetic scenario ACSZ 21-30, originating from a near-field source, produces the most destructive tsunami hazard in King Cove. The maximum wave amplitude at the tide station may reach 5 m above MHW if an  $M_w = 9.3$  event occurs nearby. It's worth noting that 1.2 m above MHW seems to be the water surface threshold at the King Cove tide station for all other synthetic scenarios. Except for the Alaska-Aleutian Subduction Zone, the South American Subduction Zone and the Kamchatka-Kuril-Japan Subduction Zone are probably the most dangerous tsunami source areas capable of causing damages in King Cove, while the most insignificant tsunami source area is Central America – an  $M_w = 9.3$  event could only produce 20-30 cm tsunami amplitude at King Cove tide gauge. Figure 21 shows ACSZ 21-30 will cause intensive flooding in King Cove including both boat harbors, and the west part of the King Cove peninsula. However, the residential areas in the eastern part of the peninsula are not affected. All other synthetic scenarios only result in mild or no tsunami flooding at King Cove (Figures 19 to 61). This indicates that King Cove will only be exposed to minor impact caused by distant tsunamis, but should always be prepared for the near-field tsunami.

All synthetic scenarios are tested with 12- to 24- hour model simulation depending on the distance of the tsunami source. All test runs are robust, and no instabilities were observed during these the test runs.

#### **4. Summary and Conclusions**

This study developed tsunami forecast and reference models for the community of King Cove, Alaska. The developed model is implemented into NOAA's forecast system to provide real-time modeling forecast of the water elevation, runup and inundation for King Cove. This study discusses the details of each individual component of the forecast model, including the bathymetry and topography, the basic model setup and model parameters. The forecast model employs grids as fine as 20 m and can accomplish 4-hour simulation after tsunami arrival in 12 mins of CPU time. A reference model was developed in parallel to provide referencing modeling results for the forecast model using grids as fine as 10 m.

Model validations were carried out for the King Cove forecast and reference models using eight historical tsunami events and comparing the modeling results to the observations at the tide station. Modeling at King Cove showed good agreement with observations when the background noise was less significant during larger events. The model validation using historical tsunamis shows that the tested events did not cause serious damage or inundation to the coastline of King Cove. This study used 43 synthetic mega events at the level of Mw 9.3 to ensure the stability of the developed forecast model under the strike of the waves up to 7m amplitude along the coastlines of King Cove.

#### **5. Acknowledgments**

This research is funded by the NOAA Center for Tsunami Research (NCTR). The author would like to thank the modeling group of NCTR for help suggestions and discussions. This publication is also partially funded by the Joint Institute for the Study of the Atmosphere and Ocean (JISAO).

Table 4 Source combination of 41 synthetic tsunami scenarios used for model testing.

## **Appendix A Model input**

Development of the King Cove, Alaska, tsunami forecast model occurred prior to parameters changes that were made to reflect modification to the MOST model code. As a result, the input file for running both the optimized tsunami forecast model and the high resolution reference inundation model in MOST have been updated accordingly. Appendix A1 and A2 provide the updated files for King Cove, Alaska.

### **A1. Reference model \*.in file for King Cove, Alaska**

```
0.001      Minimum amplitude of input offshore wave (m)
1.0        Input minimum depth for offshore (m)
0.1        Input "dry land" depth for inundation (m)
0.0025     Input friction coefficient (n**2)
1          let a and b run up
300.0      blowup limit
0.15       input time step (sec)
216000     input amount of steps
16         Compute "A" arrays every n-th time step, n=
10         Compute "B" arrays every n-th time step, n=
160        Input number of steps between snapshots
0          ...Starting from
1          ...saving grid every n-th node, n=
```

### **A2. Forecast model \*.in file for King Cove, Alaska**

```
0.0001     Minimum amplitude of input offshore wave (m)
1.0        Input minimum depth for offshore (m)
0.1        Input "dry land" depth for inundation (m)
0.0016     Input friction coefficient (n**2)
1          let a and b run up
300.0      blowup limit
0.5        input time step (sec)
57600      input amount of steps
5          Compute "A" arrays every n-th time step, n=
10        Compute "B" arrays every n-th time step, n=
60        Input number of steps between snapshots
0          ...Starting from
1          ...saving grid every n-th node, n=
```

**Appendix B. Propagation database:  
Pacific Ocean Unit Sources**

These propagation source details reflect the database as of February 2013, and there may have been updates in the earthquake source parameters after this date.

Figure B.1: Aleutian–Alaska–Cascadia Subduction Zone unit sources.

Table B.1: Earthquake parameters for Aleutian–Alaska–Cascadia Subduction Zone unit sources.

## **Appendix C. SIFT testing results**

Authors: Lindsey Wright, Yong Wei

### **1.0 PURPOSE**

Forecast models are tested with synthetic tsunami events covering a range of tsunami source locations. Testing is also done with selected historical tsunami events when available.

The purpose of forecast model testing is three-fold. The first objective is to assure that the results obtained with NOAA's tsunami forecast system, which has been released to the Tsunami Warning Centers for operational use, are consistent with those obtained by the researcher during the development of the forecast model. The second objective is to test the forecast model for consistency, accuracy, time efficiency, and quality of results over a range of possible tsunami locations and magnitudes. The third objective is to identify bugs and issues in need of resolution by the researcher who developed the Forecast Model or by the forecast software development team before the next version release to NOAA's two Tsunami Warning Centers.

Local hardware and software applications, and tools familiar to the researcher(s), are used to run the Method of Splitting Tsunamis (MOST) model during the forecast model development. The test results presented in this report lend confidence that the model performs as developed and produces the same results when initiated within the forecast application in an operational setting as those produced by the researcher during the forecast model development. The test results assure those who rely on the King Cove tsunami forecast model that consistent results are produced irrespective of system.

## **2.0 TESTING PROCEDURE**

The general procedure for forecast model testing is to run a set of synthetic tsunami scenarios and a selected set of historical tsunami events through the forecast system application and compare the results with those obtained by the researcher during the forecast model development and presented in the Tsunami Forecast Model Report.

Specific steps taken to test the model include:

1. Identification of testing scenarios, including the standard set of synthetic events, appropriate historical events, and customized synthetic scenarios that may have been used by the researcher(s) in developing the forecast model.
2. Creation of new events to represent customized synthetic scenarios used by the researcher(s) in developing the forecast model, if any.
3. Submission of test model runs with the forecast system, and export of the results from A, B, and C grids, along with time series.
4. Recording applicable metadata, including the specific version of the forecast system used for testing.
5. Examination of forecast model results from the forecast system for instabilities in both time series and plot results.
6. Comparison of forecast model results obtained through the forecast system with those obtained during the forecast model development.
7. Summarization of results with specific mention of quality, consistency, and time efficiency.
8. Reporting of issues identified to modeler and forecast software development team.
9. Retesting the forecast models in the forecast system when reported issues have been addressed or explained.

Synthetic model runs were tested on a DELL PowerEdge R510 computer equipped with two Xeon E5670 processors at 2.93 Ghz, each with 12 MBytes of cache and 32GB memory. The processors are hex core and support hyperthreading, resulting in the computer performing as a 24 processor core machine. Additionally, the testing computer supports 10 Gigabit Ethernet for fast network connections. This computer configuration is similar or the same as the configurations of the computers installed at the Tsunami Warning Centers so the compute times should only vary slightly.

## Results

The King Cove forecast model was tested with NOAA's tsunami forecast system version 3.2.

The King Cove forecast model was tested with four synthetic scenarios and one historical tsunami event. Test results from the forecast system and comparisons with the results obtained during the forecast model development are shown numerically in Table 1 and graphically in Figures 1 to 5. The results show that the forecast model is stable and robust, with consistent and high quality results across geographically distributed tsunami sources and mega-event tsunami magnitudes. The model run time (wall clock time) was 19.98 minutes for 8 hours of simulation time, and 10 minutes for 4 hours. This run time is within the 10 minute run time for 4 hours of simulation time and satisfies time efficiency requirements.

Four synthetic events were run on the King Cove forecast model. A slip of 28.4 m was used rather than the standard 25m for direct comparison purposes. Because the King Cove model was developed prior to a shift in locations for the Central and South America sources, a direct comparison between model development results and the forecast system output cannot be made for the Central and South America (CSSZ) 89-91 case. The modeled scenarios were stable for all cases tested, with no instabilities or ringing. Results show that the largest modeled height was 86.1 centimeters (cm) and originated in the Kamchatka-Yap-Mariana-Izu-Bonin (KISZ) 22-31 source. Amplitudes less than 100 cm were recorded for all test source scenarios. The smallest signal of 67 cm was recorded at the Aleutian-Alaska-Cascadia (ACSZ) 46-55 source. Table 1 shows discrepancies for the synthetic events between the SIFT results and the model results at the time of model development. This is attributed to the update of the propagation database. SIFT is using the latest database that takes account of initial source deformation over the entire computational domain, while the model development results were based on the old database that only considered the initial source deformation in a confined area. The unit source parameters in CSSZ have been updated since the model was developed. This does not allow a direct comparison between SIFT results and the results at the time of model development, and therefore CSSZ 89-98 was left blank in the columns of "Development Max" and "Development Min". The Tohoku 2011 historical event was also stable and direct comparisons of output from the forecast tool with results of both the Tohoku 2011

historical event and available development synthetic events, demonstrated that the wave patterns were similar in shape, pattern and amplitude. It's worth noting that the modeling results of 2011 Tohoku events are both using the latest propagation database, so the results are identical between SIFT and development.

Source Zone	Tsunami Source	$\alpha$ [m]	SIFT Max (cm)	Development Max (cm)	SIFT Min (cm)	Development Min (cm)
Mega-tsunami scenarios						
KISZ	A22-A31, B22-B31	28.4	86.1	73.74	-71.6	-74.09
ACSZ	A46-A55, B46-B55	28.4	66.7	70.76	-84.2	-78.93
CSSZ	A89-A98, B89-B98	28.4	80.4	-	-75.0	-
NTSZ	A30-39, B30-39	28.4	76.8	68.78	-72.7	-82.49
Historical events						
Tohoku 2011			26.6	40.02 (12-hour run) 26.63 (8-hour run)	-33.0	-37.05 (12-hour run) -32.74 (8-hour run)
